Abstract:

General government expenditure has risen steadily in recent decades. However, their scale and structure vary from country to country. Different structures and efficiencies may also affect economic growth in other ways. The study examines the relationship between the expenditure side of general government (based on the COFOG structure and database) and the GDP growth rate. The analyzes were performed on a panel database formed from the Member States of the European Union between 1996 and 2017 using OLS, fixed effect and GMM model. Based on the results, the main conclusion of this study is that the positive growth effect of education and health expenditures is delayed. In addition, the further results confirm the findings in the earlier literature regarding the correlation between public expenditure structure and economic growth.

Összefoglaló:

Az államháztartási kiadások az elmúlt évtizedekben folyamatos emelkedést mutattak. Mértékük és szerkezetük azonban eltérő az egyes országokban. Az eltérő szerkezet és hatékonyság más módon hathat a gazdasági növekedésre is. A tanulmány az államháztartás kiadási oldalának (COFOG adatbázis alapján) és a GDP növekedési üteme közötti összefüggéseket vizsgálja. Az elemzések az Európai Unió tagállamaiból 1996-2017 között időintervallumon képzett panel adatbázison kerültek elvégzésre OLS, fixed effect és GMM modell alkalmazásával. Az eredmények alapján a tanulmány fő következtetése szerint a oktatási és egészségügyi kiadások pozitív növekedési hatása késleltetve jelentkezik. Emellett a további kapott eredmények megerősítik az eddigi szakirodalmak megállapításait az állami kiadások szerkezetének és a gazdasági növekedés közötti összefüggésről.

Keywords: public expenditures, economic growth, EU, GMM, OLS, Fixed Effects Model

1. Introduction

The 20th century resulted in increasing volumes of public spending and expanding fields of government activity. This may have been due to increasing wariness of economic crises experienced in the past or voters' growing demand for social services, or to the political decision makers' inclination to increase the public budget rather than to reduce social benefits. However, this also led to a policy dilemma of whether more public or more private control over the spending of the national income will result in the prospect of higher income in the future. The economic theory about aggregate demand assumes that public finances have an additional impact on economic output. The general GDP equation in aggregate demand or national expenditure form explicitly includes the government expenditures as a component of income. This correlation between economic growth and expenditure structure is assumed by economics. The impact of public finances is measured by fiscal multipliers. (Both tax and expenditure multipliers can be calculated. In this case, the latter of these is important.) One of the major dilemmas in macroeconomics analysis is whether public spending and tax revenue can support economic growth, help recovery, counteract downturns, or, on the contrary, limit growth. For example, research in the 2010s has reinterpreted the effectiveness of the fiscal activity of the state, clearly altering the assessment of whether the financial activity of the general government may even generate growth surpluses. There appears to be an assumption that the answer is independent of the composition and quality of public revenue and expenditure. It is therefore worth analysing the composition of tax revenues and the structure of expenditures.

Halmai (2015) outlines the growth challenges confronting European economies, e.g. the fiscal structure and imbalances as growth factors. He established that the European model faced a challenge originating in the absence of a convergence mechanism, and this is why the integration mechanism became dysfunctional. He claimed that the "rebirth of convergence is both a challenge to and a precondition of European renewal and reform." Among other things, Halmai concluded that the imbalances of public finances and a need for sustainable public finances are the sources of conflicts. (Benczes (2010) collected and synthesised successful approaches in the European cases of fiscal consolidation, such as reforms and growth factors.)

An examination of the expenditure structure reveals which areas dominate fiscal policy. It is worth examining the proportion of expenditure on human capital and infrastructure, which secure long-term sustainable economic growth and competitiveness in high value-added, knowledge-intensive sectors. (For example, Darvas et al. (2018) sought the optimal level of health spending.) A structural analysis of public finances highlights the importance of the composition of fiscal austerity, the distribution of surpluses and the shift in winners' and losers' income levels by redistribution.

Empirical calculations on fiscal multipliers indicate that different types of appropriation can be of different intensities. This phenomenon implies the hypothesis of public finances that the structure of the public budget (both on the tax and expenditure side) has a significant impact on the volume of GDP. This study works on the basis of the assumption mentioned above and aims to quantify the impact of the structure of public expenditures on growth of per capita GDP.

The methodology of the study is built on a panel regression analysis of EU countries. Based on the literature review, it was necessary to use more than one model to analyse the impact of spending on different areas on GDP-growth: OLS, Fixed Effects Panel and first-differences GMM model tests were executed in EViews software on the period between 1996 and 2017 of 25 EU countries. The research question was as follows: Do the various appropriations (i.e. public spending by function) accelerate or slow down the speed of economic growth? An exact hypothesis is not formulated as the significance, the intensity and the (positive/negative) sign can differ for each type of appropriations.

2. Literature review

The literature on the impact of public finance structure on economic growth is clearly split into tax and expenditure analyses. In this study, only the literature related to expenditure is relevant. Barro (1990) laid the foundations of models of public finance structure by extending the endogenous growth models with the addition of tax-financed government services that affect production. He found that growth rates initially rise with productive government expenditures but subsequently fall when there is an increase in utility-type expenditures. However, it is not easy to be conclusive about the relationship between expenditure structure and economic growth. Barrios and Schaechter (2008) refer to Gerson (1998), Avila and Strauch (2003) and Afonso and Furceri (2008), whose results are inconclusive about the impact of expenditure structure. Their experience is that, principally, public transfers and consumption are typically estimated to have a negative impact on growth. However, Avila and Strauch (2003) estimate that EU countries' public investments have had a positive influence on growth, while Afonso and Furceri (2008) do not find EU and OECD economies' public investments to be significant in determining growth.

Several types of econometric models have been proposed in empirical studies of the correlation between public expenditures and economic growth. Kneller et al. (1999) applied econometric models to time series panel data for 22 OECD countries for the period 1970–1995. They considered five different forms of panel data estimator for each regression: pooled OLS, one-way (country dummies) fixed (by OLS), random (by GLS) and two-way (country and time effects) fixed, and random effects models. They also distinguished between productive and non-productive expenditures. Productive government expenditure was defined as spending which enhanced growth, while non-productive expenditure did not. The expenditures classified as non-productive were, significantly, proved to have equal coefficients, and consequently these variables had a zero impact on growth. An increase in productive expenditures was found to significantly enhance economic growth. Both of these results were consistent with the Barro (1990) model. This paper reached an important methodological conclusion about lagged impact: the magnitudes of the estimated impacts of productive expenditures are sensitive to the process of 5-year averaging of the data, which suggests that considerable

caution should be exercised in predicting the precise effects on growth of changes in public finances.

Boldeanu and Tache (2015) is the methodological forerunner of the current study as it analysed the correlation between public expenditure and economic growth for 30 European countries in the period of 1991–2012 with OLS, LSDV and GMM econometric models on the COFOG database. It thus served as a specific methodological pattern, and the conclusion was that most of the sub-areas of public spending affected economic growth negatively. Fölster and Henrekson (2001) analysed the OECD countries in the period of 1970–1995 with several panel regression models and measured the negative relationship between expenditure and economic growth. To quantify this, a 10% increase of the expenditure-to-GDP ratio resulted in a 0.8% decrease in growth rate value. Shijaku and Gjokuta (2013) based their empirical analysis on the GMM model. The impacts of expenditure on growth were analysed by categorising state spending into productive and non-productive expenditure. Their first finding was that government revenue growth had a higher effect on economic growth than government expenditure. The second finding was that, predictably enough, growth was affected positively by productive expenditure and negatively by non-productive expenditure.

Macek (2014) conducted a panel regression analysis of the crowding out effect on the structure of total government spending where unproductive spending (e.g. funding of the welfare state and social security) predominates, which lowers the GDP growth ratio. The analysis found that government expenditures affect economic growth negatively. He concluded that this phenomenon can probably be linked to the crowding out effect on the structure of total government spending where unproductive expenditure constitutes the majority share. Bania et al. (2007) used a GMM model to analyse the impacts on growth of taxes and government expenditures, and concluded that Barro model-style "growth hills" are present for U.S. states, which means that the incremental effect of tax-financed expenditures on productive government activities is non–monotonic and initially positive (a positive linear effect), but eventually negative. The explanation is the same as that later given by Macek (2014), that is, the decline originates in the crowding out effect of rising tax, which reduces the net return to private capital.

Beyond OLS and GMM, the application of the VAR model can also be found in the paper of Sever et al. (2011). The VAR model is not relevant to the current study,

but its results can confirm the conclusions of the current study. This VAR model resulted in the followings: the capital expenditures have a positive effect on economic growth in the short and long term; the impact of expenditures on goods and services are positive in the long term, with greater fluctuations in the short term; the current consumption, compensation of employees and subsidies in all cases indicated a negative effect on GDP in the long term; the subsidies in all specifications in the short term increase the GDP, while in the long run they affect it negatively.

Barrios and Schaechter (2008) confirm the negative correlation between public spending and economic growth although they indicate a weak positive correlation between government investments and economic growth or between education spending and education quality indicators such as functional literacy results. Such phenomena may suggest that even though in the short term the expenditure types have a negative coefficient with economic growth, a very long-term positive effect should not be excluded. Since students spend 12 or more years in the education system, spending on education has a long lagging impact. In the current analysis, the lags are used in the case of spending variables, but models and time series limited the length of the lags. The lagging on education spending was introduced from 1 to 10 in the model. Fournier and Johansson (2016) measured a negative correlation, with spending and concluded that larger governments were significantly and negatively associated with long-term growth, while the mix of spending affected the impact on GDP growth, and, according to these two determinants, the Swedish mix of public expenditures seemed to be the most growth-friendly among the OECD countries.

Table 1. Summary of the empirical literature

Study	Methodology	Database, region, period	Concrete results relevant to the impact of expenditure structure on GDP/capita growth
Barrios & Schaechter (2008)	statistical analysis	COFOG, 24 industrialized countries, 1980-2005	- growth can be supported by public expenditure oriented towards investment in human capital (education, health), R&D spending, public infrastructure
Avila & Strauch (2003)	Panel Unit Root, Panel Cointegration	AMECO, 15 EU countries, 1960-2001	- coefficient on total expenditures negative, - total public investment: positive - total transfers: negative -government consumption spending: negative
Bania et al. (2006)	GMM (Arellano-Bond style)	U.S. Census of Governments, states of USA, 1962-1997	- negative impact on growth by first lag of health & welfare expenditures of local governments (only one type of expenditure was included in the model)
Afonso & Furceri (2008)	cross-section time-series regressions	OECD Economic Outlook, OECD+EU states 1970-2004	- sizeable, negative, significant effect on growth of government consumption, subsidies, government investment
Kneller et al. (1999)	pooled OLS, fixed OLS, random GLS	World Bank data, 22 OECD states 1970-1995	- negative growth impact of non-productive expenditures - increase in productive expenditures significantly positive for growth
Boldeanu and Tache (2015)	GMM, OLS, Fixed effects panel (LSDV-estimator),	Eurostat, AMECO, 30 European states, 1991-2012	- massive negative impact of general services, public debt transactions, economic affairs, environmental affairs, health, recreation and religion (only in GMM), education, social protection (no lag was used) - positive impact of research expenditures, defence (only in GMM), public order and police - minimal positive impact of housing and community amenities, but not significant
Fölster and Henrekson (2001)	OLS	OECD data OECD countries, 1970–1995	- robust negative relationship between public expenditure and growth in rich countries - 0.7–0.8 percentage points decrease in the growth rate caused by 10 percentage points increase in expenditure ratio
Sever et al. (2011)	VAR	Croatian Ministry of Finance, Croatia, 1994-2008	- positive effects of investment spending, purchases of goods and services, capital expenditures - negative effects of other current spending
Shijaku & Gjokuta (2013)	GMM	INSTAT (ALB) Albania 1998q1-2010q4	- positive impact of productive expenditures - negative impact of non-productive expenditures - p-value 0.1, weak significance
Macek (2014)	panel regression	OECD National Accounts Stat., OECD countries 2000-2011	- lower economic growth by growth of 1st lag of government spending dominated by unproductive items
Fournier & Johansson (2016)	OLS with fixed effect	COFOG, OECD countries 1987-2014	- public investment and education support growth - pensions and public subsidies lower growth

3. Methodology and quality of data

3.1. Empirical model

The aim of this paper is to analyse the impact on GDP per capita growth rate of the structure of public expenditures. The empirical analysis of the study is built on econometric models. Three models were used, in accordance with the findings of the literature review: the first-differences Panel General Method of Moment (GMM) test, the Fixed Effects Panel test and the Ordinary Least Squares (OLS) method. Each of these three models had different limitations. The OLS results are published as a control test, but they were not considered to be decisive since this type of test is not considered to be appropriate for panel data analysis due to the possibility of inconsistent results. To avoid the limitations of the OLS test and to solve causality problems, the 2SLS model was tried. However, when this model was applied the number of instrument variables proved to be relatively few in comparison to the number of determinants. Thus, the 2SLS test was not feasible. In addition, panel data estimation techniques were also used: the fixed and random effects panel models. However, these two analytical methodologies do not address the endogeneity problem posed by each control variable. The instrument variable or IV technique is one of the methods that can be used to solve this problem. The GMM is another way to eliminate the endogeneity problem which justified its application. (It must be noted that the GMM method has disadvantage as it ignores structural breaks and cross-sectional dependencies). The context and the different types of the GMM method have been extensively considered in the literature, for example by Arellano and Bond (1991), Arellano and Bover (1995) and by Blundell and Bond (1998). The comparison of GMM and Fixed Effects Panel test results is an established practice in the empirical literature as demonstrated by Fidrmuc and Degler (2019), among others.

In the model used in the current research, the dependent variable is the annual change of real GDP per capita in constant prices as a percentage. The determinant variables were distributed into two groups for methodological reasons. The first group – related to the research question – contains the different types of expenditure variables. The data source is the UN COFOG database about general government annual expenditure by function as a percentage of GDP, at the two-digit level as follows:

- GF01 General public service

- GF02 Defence
- GF03 Public order and safety
- GF04 Economic affairs
- GF05 Environmental protection
- GF06 Housing & community amenities
- GF07 Health
- GF08 Recreation, culture, religion
- GF09 Education
- GF10 Social protection

The other group of determinants contain other factors of GDP which were treated as so-called instrument variables in the GMM model version. Some of these variables relate to the short-term utilisation of GDP, from the Eurostat 'GDP and main components' annual database, taken as a GDP percentage.

- Household Consumption (HC) (Eurostat: P31_S14 Final consumption expenditure of households)
- Investment (GFCF) (Eurostat: P51G Gross fixed capital formation)
- Net Export (NX) (Eurostat: P6–P7 Exports of goods and services – Imports of goods and services)

Other determinant and instrument variables are long-term factors, related to the Solow-Swan economic model of growth:

- Population change (POP) – Demographic balance and crude rates at the national level, Total population change – percentage (Eurostat)
- Total Factor Productivity (TFP) – percentage changes (OECD)

The change of GDP is assumed to be determined by the initial level of development.[1] To incorporate this economics thesis into the model, the lagged logarithmic value of GDP per capita (GDP_PC_{t-1}) is applied as determinant which is calculated in international dollar on purchasing power parity base, constant prices (2017=100). The data was imported from The World Bank Data.[2]

Finally, a dummy variable was introduced to take into account and test the impact of monetary integration, which is relevant in the EU. In the period from 1996–2017, of the 28 EU countries eleven introduced the euro in 1999–2001, and eight others after 2009. As the literature of integration economics attributes a growth effect to participation in the single currency zone, it is reasonable to apply this

[1] See: Barro, 1991.

[2] (https://data.worldbank.org/, download, 17th June 2020)

variable. The EURO Dummy (D_{eur}) is 1 if the country was a euro zone member in the given year, and 0 if not.

Based on the above variables and grouping system, the basic equation of the current OLS and Fixed Effects Panel model including determinants is as follows:

$$gpd\_pc\_gr_{i,t} = \alpha + \beta_1 \ln\ gdp\_pc_{i,t-1} + \beta_2 GF01_{i,t} + \beta_3 GF02_{i,t} + \beta_4 GF03_{i,t} + \beta_5 GF04_{i,t} + \beta_6 GF05_{i,t} + \beta_7 GF06_{i,t} + \beta_8 GF07_{i,t} + \beta_9 GF08_{i,t} + \beta_{10} GF09_{i,t} + \beta_{11} GF010_{i,t} + \beta_{12} HC_{i,t} + \beta_{13} GFCF_{i,t} + \beta_{14} NX_{i,t} + \beta_{15} POP_{i,t} + \beta_{16} TFP_{i,t} + \beta_{17} Deur_{i,t} + u_{i,t}\ , \quad (1)$$

where i denotes each country, t is a time horizon, while $t-1$ is a lagged version of the given variable, and $u_{i,t}$ is an error term.

The basic equation of the current GMM model including determinants and instrument variables is thus:

$$gpd\_pc\_gr_{i,t} = \beta_1 \ln\ gdp\_pc_{i,t-1} + \beta_2 GF01_{i,t} + \beta_3 GF02_{i,t} + \beta_4 GF03_{i,t} + \beta_5 GF04_{i,t} + \beta_6 GF05_{i,t} + \beta_7 GF06_{i,t} + \beta_8 GF07_{i,t} + \beta_9 GF08_{i,t} + \beta_{10} GF09_{i,t} + \beta_{11} GF010_{i,t} + u_{i,t}\ , \quad (2)$$

The GMM model separated the variables into independent and instrument variables, while the Fixed Effects Panel and the OLS test considered all of them to be determinants (dependent and control variables). As instrument variables the components of GDP were used, including household consumption, net exports, GFCF, population change and total factor productivity, since these variables are potentially endogenous. Furthermore, according to the GMM model versions of the Arellano-Bond form, a 1st lag of the dependent variable (GDP_PC-GR_{t-1}) was inserted among the instrument variables to improve the significance of the results and to address the endogeneity problem.

An extended formula was used for the GMM model. First, the aforementioned 1st lag of the dependent variable was included as an instrument variable to increase the significance of the coefficient related to the determinant variables. Second, the determinant spending on education and health (GF07 and GF09) was tested with and without lags. The rationale for the lagged GMM model version is a simple economics intuition that the educational programs, vocational trainings, medication and healing has a delayed effect, because productivity and capacity advantages can be realized after students finish the school or patients leave the hospital. This can have a longer lagging positive impact from human resource spending similar to the J-curve effect related to current account adjustment policy.

3.2. Data

The database is based on the annual time series data of 25 EU countries and their time series in the period from 1996 to 2017. Of the 28 EU countries, the following three had to be omitted because of missing data or because they were outliers: Slovenia, Croatia and Luxemburg. Data sources for Slovenia were incomplete for some variables. Croatia was not part of the European Union for the majority of the period examined which resulted in a lack of available data. Luxembourg, due to its size, would have caused a significant positive bias in the estimates of our models. The descriptive statistics of the variables are shown in Table 2.

Before the model-based examinations, the stationarity of the data series must be examined. The Levin-Lin-Chu[3] panel unit root test was used to examine the stationarity of the time series. Based on the unit root test, three variables (GF08 Culture, Households final consumption, Net export) cannot be considered as stationary, which was particularly improved by the implementation of first difference values.

In panel regression approaches, fixed and random effect methods can be applied. In order to decide which panel method is relevant to our database, we applied the Hausman test. In this case, the Hausman test with 0.0000 probability indicator decided that Fixed Effects Panel test is appropriate.

4. Results

In the assessment of the results in *Table 3*, the focus is on the GMM model coefficient, while the Fixed Effects model results are the controls. The OLS model numbers are published only because this type of econometric model has been used in the existing literature related to the topic, and although it is not adequate enough for panel econometrics, it is, however, much more suitable for time series analysis, as previously stated. For the GMM model, the Arellano-Bond (AR) autocorrelation test was applied to exclude the time series correlations between the observations. The Hansen-J test was also used to eliminate over-identification of instruments. The obtained test results were satisfactory, and can be used to interpret the results of the model.

According to the GMM model coefficients, it can be established that not every COFOG category has an impact on economic growth at a 5% level of significance for the panel of 25 EU countries in the period 1996-2017. Examples of such areas are the spending on Defence (GF02), Economic Affairs (GF04), Environment (GF05), Housing (GF06), Culture (GF08) and Social protection (GF10). Besides, Education (GF09) was significant and indicated very big effect but had negative sign. Health (GF07) with positive sign and Social protection (GF10) with negative sign became significant at 1%. It must be established that General Public Service (GF01) was measured to be significant at 1% with negative sign in both GMM version. This phenomenon was confirmed by the Fixed Effects Panel model, too, although, merely with smaller coefficient.

The version with lagged spending on human resource factors confirmed the significance of Public order (GF03) and Education (GF09), but resulted in opposite sign. The impact sign of spending on education turned to be positive in the version modified by lagging, thus, the economics intuition previously stated can be confirmed that spending on human resource (health and education) supports the economic growth, however it might require longer time. The Fixed Effects Panel model without lagged COFOG variables did not indicate significance at 5% in case of GF02, GF05, GF06, GF07, GF08, while Education (GF09) had negative sign.

The negative effect sign can be interpreted as the spending multiplier of these appropriations being less than one, that is to say, one euro spent results in less than one additional euro in the total absolute income. It is common knowledge in

macroeconomics that, on the one hand, the state is not an efficient spender of money, and on the other hand, public services are the result of market failures as market demand and supply cannot compete with each other in equilibrium price and quantity. That is why the state should perform these services with optimum efficiency and finance them from tax revenue collected from the market participants.

Because of the intuition mentioned above about spending on human resource, it was imperative to detect delayed effects on human resource spending in order to indicate a positive effect. For this reason, the GMM model was finetuned with joint lagging of GF07 (Health) and GF09 (Education). The lags went from 1 to 3 years and were shifted. The results of the lagged tests are as follows:

- lag 1 resulted in a positive coefficient in case of GF07, but, in case of GF09 it was negative and insignificant,
- GF07 lagged with 2, GF09 lagged with 1 resulted in positive coefficient, but GF09 was insignificant,
- GF07 lagged by 1, GF09 lagged by 2 resulted in a positive coefficient, GF07 was significant at 1%, GF09 was insignificant,
- lag 2 in both variables resulted in a positive coefficient and both of them were significant at 1%,
- GF07 lagged by 3, GF09 lagged by 2 resulted in positive coefficients, and both of them were significant at 1%.
- GF07 lagged by 2, GF09 lagged by 3 resulted in positive coefficients, but significance was 10% in case of GF09, 1% in case of GF07.
- (It should be noted that single lagging of education was also tested from 1 to 7 years, and the result was that the education coefficient was positive and significant at 1% for lags of 1, 2, 3 and 4. Higher lags resulted in insignificant coefficients.)

On the basis of the lagging results above, the analysis included the model version with lag 2 of GF07 and lag 2 of GF09, as it proved to be the most significant of the two coefficients.

Despite the endogeneity problem, the Fixed Effects Panel model is useful for checking the short- and long-term assumptions of macroeconomics about economic growth. The GMM model does not result in a coefficient related to its

instrument variables, but in the Fixed Effects Panel model these are determinants and thus have a coefficient. Household consumption, net export became significant, but negatively correlate with GDP growth (not only in the Fixed Effects Panel, but also in the OLS model). Significant effect was measurable in case of change of population with negative sign and the productivity represented by TFP with positive sign on GDP growth rate. The euro membership dummy was not significant in the Fixed Effects Panel, which should mean that participation in the euro zone does not affect the growth ratio. This junction does not belong to the core of the current research, which is why the conclusion drawn from the calculation is merely stated here, but not interpreted and analysed further.

Table 3. Results of regression models

Variables	GMM without lags	GMM lag GF07 (-2) lag GF09 (-2)	Fixed Effects Panel	OLS
log (GDP_PC_{t-1})	-10.62129***	-13.32526***	-1.207927*	0.061398

GDP_PC_{t-1} is the 1st lag of GDP/ capita on PPP in international dollar, constant prices.*

5. Discussion and conclusion

The results are closely concordant with the previous studies referred to in the literature review. Public spending on different budget areas in the EU can have either negative or positive effects on the GDP growth rate, according to the literature and the current results. Considering various concrete spending items, our results support the conclusion of papers which identify 'productive' and 'non-productive' expenditures. Kneller et al. (1999), Shijaku and Gjokuta (2013) established that productive expenditures are indeed positive for growth. Other studies can be grouped together with them, which found a positive coefficient for education and/or health spending, such as Fournier and Johansson (2016) or Barrios and Schaechter (2008). The COFOG-based results of the present study agree with the positive correlation when estimating with lagged health and education determinants. The current paper does not support the conclusions of Bania et al. (2006) and Boldeanu and Tache (2015) regarding the negative impact of health and education spending.

It is difficult to relate the results of this research to the positive context of public investments and public R&D spending mentioned in these papers, since the COFOG nomenclature hides the total public spending on investments and classifies it in other dimensions. Nevertheless, based on the results of the present study, the category of 'economic affairs' could not be confirmed to have a positive impact.

There is an accordance between the current results and the reviewed literature (enlisted in Table 1) with regard to welfare or non-productive expenditures. All of the authors reviewed formed a negative judgment of the impact on growth of such expenditures. (Avila and Strauch (2003) came to such a conclusion about transfers, Bania et al. (2006) about welfare expenditures, Afonso and Furceri (2008) about subsidies, Kneller et al. (1999) and Shijaku and Gjokuta (2013) and Macek (2014) about non-productive items, Boldeanu and Tache (2015) about social protection and Fournier and Johansson (2016) pensions and public subsidies.) The COFOG classification of social protection was proved to be negative, statistically significant and robust by confirming with all of the applied models and model versions in the current analysis.

The closest comparison can be made with the study by Boldeanu and Tache (2015) which is based on COFOG data base and uses GMM, OLS and Fixed Effects Panel

methodology without lagged COFOG variables. Their conclusions and the current results are consistent in relation to the positive impact of spending on public order and defence – but only when there were no lags of spending determinants – and the negative coefficient of expenditures on general public services (which is also confirmed by Sever et al. (2011)), economic affairs and social protection. Examining the effect of environmental spending, the current coefficient could not confirm their findings on its significance, robustness and negative nature. In case of culture (recreation and religion), the negative sign is coincident but the significance cannot be confirmed. The two studies came to opposite conclusions about government housing expenditures. Boldeanu and Tache (2015) estimated a minimal but statistically not significant positive impact, while the current analysis found a negative effect without statistical significance. Analysing the effect of education and health expenditures, Boldeanu and Tache (2015) used only current year determinants, which resulted in a significant negative coefficient. The current calculations confirm it merely in case education in the GMM version without lagging, but disagree in case of health spending. However, our economics intuition suggested conducting the test with lagged education and health variables. Finally, the version with a 2nd lag of both appropriations resulted in the positive effect of human capital investments, contrary to the conclusion arrived at by Boldeanu and Tache (2015).

The novelty of the current article is that lagging of determinants enabled the impact of education and health spending to be finetuned and was able to show the coefficients of these productive expenditures to be both positive and significant, when drawing on the COFOG database. It can be established that certain types of government spending can have a positive, accelerating effect on economic growth, but with a delayed impact. It is reasonable to carry out future research to uncover and explain the delayed multiplier impact on economic growth emerging from different types of public expenditure.
